

Astronomical Optics

4.3. Phase correction in interferometers

OUTLINE:

Phase referencing in interferometers

- why phase referencing? beyond V^2 interferometry: astrometry, image synthesis, phase closure

Wavefront correction on individual apertures

tradeoff between calibration accuracy, efficiency and wavefront quality

Technology:

- delay lines
- atmospheric dispersion compensation: vacuum delay lines, ADCs
- Adaptive optics correction in interferometers
- Calibration of residual phase errors with spatial filtering: pinhole, fiber interferometry

Delay lines

Must maintain near-zero Optical Pathlength Difference (OPD) between arms of the interferometer

The VLTI Delay Line

VLTI delay line moving cart

Keck interferometer coarse delay lines

Part 1:
Control and calibration of visibility in
interferometers

Scientific motivation

Why is fringe visibility accuracy important ?

Example below shows effect of fringe visibility measurement accuracy on measurement of stellar diameters (in this example, used to measure absolute distance to Cepheid stars)

$$V^2(B\theta/\lambda) = \left(2 \frac{J_1(\pi B\theta/\lambda)}{\pi B\theta/\lambda} \right)^2$$

Figure 1. Different interferometric attempts to measure Cepheid angular diameter variations. From left to right: Mourard et al. (1997⁶), Lane et al. (2000⁷) and Kervella et al. (2004⁸). The left panel is V^2 as a function of phase, while the panels to the right are angular diameters with respect to phase. The thin, continuous line is the integration of the pulsation velocity (distance has been adjusted). From left to right, one can see the effect of increasing resolution ($B\theta/\lambda$) and improving precision ($\sigma V^2/V^2$). In the left panel, the pulsation was not claimed to be detected; the middle panel was the first detection, with a 10% precision on the distance; the right panel displays one of the best: 4% in the distance.

Sources of fringe visibility loss (discussed in next slides)

What can go wrong ? Why would the measured fringe visibility be < 1 on a point source ?

Amplitude difference between the 2 beams

Problem: If one beam is brighter than the other, fringe visibility < 1

- measure flux in each arm of the interferometer

Phase errors within each of the 2 beams

Problem: Wavefront is not flat before entering the beam combiner

- calibrate visibility loss by observing another star
- good adaptive optics for each of the telescopes
- spatial filtering to clean the beams, at the cost of flux

Phase between the 2 beams is changing within detector exposure time

Problem: Measurement is superposition of shifted fringes, with apparent $V < 1$

- calibrate visibility loss by observing another star
- reduce / calibrate internal sources of vibration
- if possible, fringe tracking on nearby bright source

Phase between the 2 beams is changing within the spectral band of the measurement

Problem: Dispersion in atmosphere and interferometer: measurement is superposition of shifted fringes, with apparent $V < 1$

- optically compensate atmospheric dispersion
- calibrate visibility loss by observing another star
- disperse fringes on detector
- use vacuum delay lines

Polarization is different between the 2 beams

Problem: internal instrumental polarization in interferometer

- calibrate visibility loss by observing another star
- design telescopes, beam transport and delay lines to minimize differential polarization effects

Fringe visibility loss: phase errors in beams

Example:

2 beams are combined with a beam splitter

Each beam has phase errors, and differential phase error between the beams is ~ 1 rad
consider 3 points in the pupil:

- point 1: phase difference between 2 beams is -1 rad
- point 2: phase difference between 2 beams is 0 rad
- point 3: phase difference between 2 beams is +1 rad

for each of the
3 points,
visibility is = 1,
but phase is
offset

What is observed is the total flux, the sum of
the 3 curves on the left

Measured visibility = $0.7 < 1.0$

problem:

Is measured visibility due to aberrations, or
true object visibility

Same concept applies to variations of phase
with time and wavelength

Fringe visibility loss: phase errors in beams

Solutions to problem

Visibility loss is approximately equal to Strehl ratio $\sim \exp(-\sigma^2)$

With $\sigma = 1$ radian RMS, visibility ~ 0.3

Good **adaptive optics correction** to reduce σ is essential on large telescopes

Spatial filtering can be used to clean beam:

Optically transforms aberrated wavefront into flat wavefront

With aberrated wavefront, light is lost by spatial filtering

Spatial filtering

Spatial filtering alone does not help, as flux variations in interferometer arms are strong

Photometric calibration, achieved by measuring light in both arms of the interferometer AFTER spatial filtering, can calibrate visibility loss due to flux variations.

Spatial filtering + photometric calibration is powerful solution, and has achieved $< 1\%$ visibility accuracy on sky

IOTA fiber interferometer (Berger et al. 2001)

Fringe visibility loss: chromatic dispersion

Atmosphere introduces strong chromatic dispersion which needs to be compensated
In conventional interferometer, delay line introduces a delay (in air) to compensate for a vacuum delay $\rightarrow$ dispersion compensator is required.
Problem can be mitigated by using vacuum delay lines

Part 2:

Control and calibration of fringe phases

Fringe tracking: essential to allow observation of faint sources

Throughput in an interferometer is often low, due to large number of optical elements:
telescope, beam transport, delay lines, beam combiner

Atmospheric turbulence and vibrations move fringes very rapidly

Measurement is only possible if individual exposure time $\ll$ time it takes for fringe to move by a wavelength $\rightarrow$ with no phase tracking, difficult to observe faint targets

Typical limiting magnitudes for interferometers: 5 to 10 in visible / near-IR

To extend this limit, one needs to track and lock fringes to allow long exposures

Observations typically requires 100-1000 Hz sampling to “freeze” the seeing.

Consider fringe sensing carried out in K band (2.0-2.4 microns):

- an 8 m aperture receives $\sim 15,000$ photons from a $K=10$ star in 1 ms.

- sky background is ~ 1500 photons/ms.

- Telescope background is $\sim 15,000$ photons/ms.

- throughput is 6%.

- This gives an SNR of 8 in a 1 ms exposure.

Fringe tracking

Fringe tracker measures rapidly fringe position, and actively controls optical pathlength corrector (=fast delay line) at the input of the beam combiner

Enables longer exposures with the scientific instrument

VLT fringe tracker shown at the upper left corner of this figure (Corcione et al., 2008)

Phase referencing

Scientific motivations

Image reconstruction with multiple baselines requires measurement of phases and visibilities (with no phases, only centro-symmetric component of the image can be estimated)

Astrometric measurement (measuring position of sources) requires fringe phase

On a single baseline: astrometric error [rad] = phase error [rad] $\times$ ($\lambda / 2\pi$) / Baseline

How to reference phase ? - or what to use as a reference

A **nearby star** can be used to reference phase on a single baseline interferometer

Phase closure relationships can be used to separate instrumental phases from object phases (see next slides)

Phase can be measured as a function of wavelength:

object itself (at different wavelength) provides a reference

Example:

Accurately measuring photocenter as a function of wavelength with an interferometer can reveal planets, as hot planet is redder than star

See VLTI/Amber instrument for example

Phase closures

The fringe packet moves back and forth in an interferometer, due to phase changes that are caused by the atmosphere.

This variation causes the real phase to be unmeasurable for a single object.

Individual phases change with atmospheric terms, α :

$$\phi_{12} = \theta_{12} + \alpha_1 - \alpha_2$$

$$\phi_{23} = \theta_{23} + \alpha_2 - \alpha_3$$

$$\phi_{31} = \theta_{31} + \alpha_3 - \alpha_1$$

Define a **closure phase** which gets rid of the atmosphere:

$$\Phi_{123} = \phi_{12} + \phi_{23} + \phi_{31} = \theta_{12} + \theta_{23} + \theta_{31}$$

There are $(N-1)(N-2)/2$ closure phases in an array.
3: 1 closure phase, 3 visibilities -> 33% of phase information recovered.

10: 36 closure phases, 45 visibilities -> 80% of phase information recovered.

Good Reference: Monnier 2007

Fig. 4. Phase errors introduced at any telescope causes equal but opposite phase shifts in adjoining baselines, canceling out in the *closure phase* (see also Readhead et al., 1988; Monnier et al., 2006a).

Example 1 from Monnier 2007

Example 2 from Monnier 2007

Possible Project: Aperture Masking

Any optical system can be used as an interferometer by masking it into a set of discrete elements.

This approach is often useful for probing the spatial structure of objects that are near the resolution of the system. Possible science drivers include disks, faint companions, outflows around stars, etc.

Design an aperture masking setup for any current or planned optical facility (Keck, LBT, JWST, GMT, TMT).

Some areas to consider:

- wavelength

- aperture size and number

- layout of the array of apertures

Possible Project: LBTI upgrade (write Phil's next proposal)

LBTI has a 3-5 micron and 8-13 micron imager with 10 and 7" FOV respectively. However, the beamcombiner delivers a 60" FOV to two unpopulated camera ports. LBT also already has a 1-2.5 micron interferometer (LINC-NIRVANA) with a 10" FOV. Consider designing an add-on instrument to LBTI that uses existing AO on each port.

What should the science focus be? (disk spectroscopy?, astrometry?)

The camera needs a phase sensor. How would this get implemented?

Need a sketch of optical solution to do both phase sensing and science channel.
